Abstract—Response time is an important factor for every software system and it becomes more salient when it is associated with introducing novel technologies, such as Web services. Most performance evaluation of Web services are focused toward composite Web services and their response time. One important limitation of existing work is in the fact that only constant or service exponential time distribution are considered. However, experimental results have shown that the Web services response times are typically heavy-tailed, in particular, if there are heterogeneous. So, heavy-tailed response times should be considered in the dimensioning Web services. In this study, we propose analytical formulas for mean response times for structured BPEL constructors such as sequence, flow and switch constructors, etc. The difference with previous studies in the literature, is that we consider heterogeneous servers, the number of invoked elementary Web services can be variable and the elementary Web services response times are heavy-tailed.

Keywords: composite Web service, BPEL constructors, response times, heavy-tailed.

I. INTRODUCTION

Service-oriented computing utilizes services to support low-cost, flexible software. The underlying services are loosely-coupled, thus allowing rapid change of such systems. Although a framework for defining the functional interfaces of Web services has been established, non-functional properties remain under-development. The Web services architecture is defined by W3C (The World Wide Web Consortium) in order to determine a common set of concepts and relationships that allow different implementations working together. The Web services architecture consists of three entities, the service provider, the service registry and the service consumer. The service provider creates or simply offers the Web service. The service provider needs to describe the Web service in a standard format WSDL (Web Service Description Language), which is often XML, and publish it in a central service registry UDDI (Universal Description, Discovery and Integration). The service registry contains additional information about the service provider, such as address and contact of the providing company, and technical details about the service. The service consumer retrieves the information from the registry and uses the service description obtained to bind and to invoke the Web service, using the SOAP (Simple Object Access Protocol) protocol.

Elementary Web services, such as described by WSDL, are conceptually limited to relatively simple functionalities modeled through a collection of simple operations. However, for certain types of applications, it is necessary to combine a set of individual Web services to obtain more complex Web services, called composite or aggregated Web services. This last is possible using BPEL4WS (Business Process Execution Language For Web Services) standard, which is the result of the merger of the previous languages such WSFL (Web Services Flow Language) and XLANG (XML Business Process Language). One important issue within Web service composition is related to their Quality Of Service (QoS), which must be guaranteed for an adhesion clients. Web services quality of services is a combination of several properties and may include availability, security, response time, and reliability of Web services. For this, quantitative methods are needed to understand, to analyse and to operate such large infrastructure.

The goal of our research is to propose an extension of a recent study [1], where we have taken into account different statistical characteristics for the services and a random number of invoked services and Web service response time are supposed exponential with different parameters, contrarily to the models presented by Manascé [2] and Sharf [3]. However, most existing work only considers constant or exponential service times. As will be shown in [15][5], measurements in the WWW and in e-commerce systems have observed heavy-tailed server response time distributions. In this study, we take into account the fact that the Web services response time is typically heavy-tailed, like Pareto distribution, which is attributed to the burstiness of arriving requests [15]. More precisely, the objective of this paper is to consider the heavy-tailed response times in the dimensioning of web service platforms.

The rest of the paper is structured as follows. Section II presents the related work. Section III details the different structured BPEL constructors. Section IV presents analytical formulas for response time of these constructors. In section V, we give the response time formula for multi-choice pattern which is a generalization of switch constructor. Numerical results are given in section VI. Finally, section VII concludes and gives some perspectives to this work.

II. RELATED WORK

Major works in the domain of Web services performance are concentrated towards composite Web services and their response time. Although there have been several studies reported on the workload characterization of general Web servers, where the response-time distribution is found to be heavy-tailed, which has been attributed to the heavy-tailed nature of request and response file-sizes [15][6]. However, most existing work only considers constant or service exponential time distribution. Only few studies have been taken into account this result on the computation of composite Web services response time. Actually, the execution of a composite service have been studied as a fork-join model in [2], where Web services response time are supposed exponential with the same parameters, excepted one which is slower than others. This model states that a single Internet application invokes many different Web services in parallel and gathers their responses from all these launched services in order to return the results to a client. Sharf [3] studies the response time of a centralized middleware component performing largescale composition of web services. This last work is similar to the first study [2], that analyzes the effects of exponential response times. The work is more oriented towards studying fork-join model in order to understand the merger of results from various servers. More recently, [26] proposed how service providers can optimally allocated to support activities of business processes with topologies that can include any combination of BPEL constructors. However, authors are content to propose a general formula for a given composite Web service without giving the exact result when the service of elementary Web services are know. The exact response time of fork and join system, under some hypothesis, can be found in [7]. However, these last state that the number of servers is equal to two, the job arrival is Poisson process and the tasks have exponential service time distribution. Nelson and Tantawi [8] proposed an approximation in the case where the number of servers is greater or equal to two and homogeneous exponential servers. Thereafter, a more general case is presented in [9][10], where arrival and service process are general. An upper and lower bound are obtained by considering respectively $G/G/1$ and $D/G/1$ queuing parallel systems. Klingemann and al. [11] use a continuous Markov chain to estimate the execution response time and the cost of workflow. In [11], authors propose an algorithm which determines the QoS of a Web service composition by aggregating the QoS dimensions of the individual services, based on a collection of workflow patterns defined by Van der Aalst’s and al. [12], where Web services response times are supposed constants. These QoS include upper and lower bounds of execution time as well as throughput. In [13], we have studied end-to-end response time for composite Web services representing a factor of Internet overhead in the execution model, using simulation technique. Contrarily to these previous studies, where the servers are not heterogenous, their number is always constant and their response times are supposed exponential, the aim of this paper is to overcome these limitations. Thus, we propose analytical formulas for mean response time of composite Web services assuming that servers are heterogenous, the number of invoked elementary Web services can be variable.

III. BPEL CONSTRUCTORS

Business Process Execution Language for Web services (BPEL4WS) has been built on IBM’s WSFL (Web Services Flow Language) and Microsoft’s XLANG (Web services for Business Process Design) and combines accordingly the features of a block structured language inherited from XLANG with those for directed graphs originating from WSFL [14]. The language BPEL is used to model the behavior of both executable and abstract processes.

- An abstract process is a not an executable process and which is a business protocol, which use process descriptions that specify the mutually visible message exchange behavior of each parts involved in the protocol, without revealing their internal behavior.
- An executable process specifies the execution order between a number of activities constituting the process, the partners involved in the process, the messages exchanged between these partners and the fault and exception handling specifying the behavior in cases of errors and exceptions.

In the BPEL process each element is called an activity which can be a primitive or a structured one. The set \{invoke, receive, reply, wait, assign, throw, terminate, empty\} are primitive activities and the set \{sequence, switch, while, pick, flow, scope\} are structured activities.

In this paper, we are interested on the sequence, flow and switch activities also called constructors. In the following, we give analytical formulas to evaluate the response times to each considered constructor.

IV. RESPONSE TIMES OF STRUCTURED BPEL CONSTRUCTORS

In this section, we give analytical formulas for mean response times for structured BPEL constructors and we consider the case that the execution time of each elementary Web service $s$, of a composite Web service $S$, is heavy-tailed and we consider also that the number of invoked elementary services are variable. The Pareto function distribution is given by the following equation :

$$F(t) = \begin{cases} 0 & t \leq k \\ 1 - (\frac{t}{\lambda})^\alpha & t > k \end{cases}$$

for $\alpha < 2$ and is then heavy-tailed.

Thus, we consider in the following the control patterns supported by BPEL standard. More specifically, the control patterns considered are: sequence, parallel split (flow), exclusive choice (switch), multi-choice. This last pattern is not directly supported by BPEL, but we can implement it using control links inherited from WSFL.
A. Computation for the sequence constructor

The sequence constructor correspond to a sequential execution of $s_1$ to $s_n$ elementary Web services. The analytical formulas of mean response time $E(T_{\text{sequence}})$ is given by the following proposition:

Proposition 1: When elementary Web services $s_i, i = \{1, ..., n\}$ are exponentially distributed, the mean response time of composite Web service $S$ is given by:

$$E(T_{\text{sequence}}) = \sum_{i=1}^{n} E(T_i)$$  \hspace{1cm} (2)

Proof: The execution time of composite Web service $S$ composed by $n$ elementary Web services is given by: $T_{\text{sequence}} = \sum_{i=1}^{n} T_i$ which is easier to derive from equation (2).

Case of homogeneous servers. In the case where $T_i, i \in \{1, ..., n\}$ are random variables with Pareto distributions with parameters $(\alpha_i, k_i)$ for each $T_i$, the mean response time of composite Web service $S$ is trivial and is given by:

$$E(T_{\text{par}}) = n \frac{k \alpha}{\alpha - 1}$$

Case of heterogeneous servers. As we notice before, we overcome the limitation of other studies by considering that the servers are heterogeneous. Thus, we consider that the execution time of $k$ elementary services $s_i$ follow a Pareto distribution with rate $(\alpha_1, k_1)$ and the execution time of $n - k$ services follow a Pareto distribution with rate $(\alpha_2, k_2)$. Thus, the response time for a composite Web service $S$ is given by:

$$E(T_{\text{par}}) = \frac{k_1 \alpha_1}{\alpha_1 - 1} k + \frac{k_2 \alpha_2}{\alpha_2 - 1} (n - k)$$

B. Computation for the flow constructor

One of the most important benefits of the component approach is the interoperability. This inherent interoperability that comes with using vendor, platform, and language independent XML technologies and the ubiquitous HTTP as a transport mean that any application can communicate with any other application using Web services. Thus, the client only requires the WSDL definition to exchange message with the service. However, in the WSDL language, the elementary Web services are conceptually limited to relatively simple operations. In fact, for certain types of applications it is necessary to combine a set of elementary Web services into composite Web services. These services are generally invoked in parallel, using the flow constructor. Thus, in this section, we are focused on the mean response time of a composite Web service $S$ which is composed by $n$ elementary services invoked in parallel. In [2], the author gives an analytical formula for the response time of flow constructor but he supposes that $n$ is fixed and elementary Web services are exponential service time distribution. Our contribution is to consider that $n$ is random and Web services are heterogenous.

In the following, we give an analytical expression for the mean response time:

$$E(T_{\text{flow}}) = \sum_{i=1}^{n} \int_{0}^{\infty} t f_i(t) \prod_{j \neq i} F_j(t) dt$$  \hspace{1cm} (3)

where:

$$T_{\text{flow}} = \max\{T_i, i = 1, ..., n\}$$

As we assume that the random variables $T_i$ are independents, the cumulative function of random variable $T_{\text{flow}}$ is given by:

$$F(T_{\text{flow}}) = P(T_{\text{flow}} \leq t) = \prod_{i=1}^{n} F_i(t)$$

Thus the probability density of $T_{\text{flow}}$ is:

$$f_{T_{\text{flow}}}(t) = \sum_{i=1}^{n} f_i(t) \prod_{j \neq i} F_j(t)$$  \hspace{1cm} (4)

Thus $E(T_{\text{flow}})$ can be easily derived.

Case of Pareto distributions. We give in the following the mean response time analytical formula where the random variables $(\alpha_i, k_i), i \in \{1, ..., n\}$ are Pareto distributed with parameters $(\alpha_i, k_i)$ and $E_i \in P(E_n \setminus \{i\})$ the sub - set of $E_n$ without $i$.

Proposition 1: When elementary Web services $s_i, i = \{1, ..., n\}$ are exponentially distributed, the mean response time of composite Web service $S$ is given by:

$$E(T_{\text{sequence}}) = \sum_{i=1}^{n} \frac{k \alpha}{\alpha - 1}$$

and $P(E_n \setminus \{i\})$ the sub - set of $E_n$ without $i$.

Proof: From equation 4, the probability density of random variable $T_{\text{par}}$ is given by:

$$f_{T_{\text{par}}}(t) = \left\{ \begin{array}{ll} 0 & \text{if } t \leq \max\{k_i, i = 1, ..., n\} \\ \sum_{i=1}^{n} \prod_{j \neq i} (1 - \left(\frac{k_j}{t}\right)^{\alpha_i}) & \text{else.} \end{array} \right.$$  \hspace{1cm} (5)

As we have:

$$\prod_{j \neq i} (1 - \left(\frac{k_j}{t}\right)^{\alpha_i}) = \sum_{X \in P(E_n \setminus \{i\})} (-1)^{|X|} \prod_{j \in X} \left(\frac{k_j}{t}\right)^{\alpha_j}$$

Thus, the average response time is:

$$E(T_{\text{par}}) = \sum_{i=1}^{n} \frac{k \alpha}{\alpha - 1}$$

As we have:

$$\int_{\beta}^{\infty} t^{-\sum_{j \in X} \alpha_j - \alpha_i} dt = \frac{\beta^{-\left(\sum_{j \in X} \alpha_j + \alpha_i - 1\right)}}{\sum_{j \in X} \alpha_j + \alpha_i - 1}$$
Thus we obtain that the mean response time for a composite Web service $S$ is given by the following formula:

$$E(T_{par}^{flow}) = \sum_{i=1}^{n} \alpha_i k_i n \left( \frac{\sum_{m=0}^{n-1} (-1)^m k^{(-m+1)\alpha_i} (k^a)^m}{\sum_{j=1}^{n-1} \alpha_j + \alpha_i - 1} \right) \prod_{j \in X(X \setminus \{i\})} \alpha_j k_j$$

Case of homogeneous servers. In the case where all elementary service times are Pareto distributed with rates $(\alpha_i, k_i) = (\alpha, k)$ (i.e. $\forall i \in \{1, ..., n\}$), $\alpha_i = \alpha$, $k_i = k$. In this case the response time for $S$ is given by:

$$E(T_{par}^{flow}) = n:\kappa^\alpha \sum_{m=0}^{n-1} (-1)^m k^{(-m+1)\alpha} (k^a)^m \frac{\sum_{j=1}^{n-1} \alpha_j + \alpha - 1}{\sum_{j=1}^{n-1} \alpha_j + \alpha - 1} C_{m-1}^{n-1}$$

Where:

$$C_{m-1}^{n-1} = \frac{(n-1)!}{m!(n-1-m)!}$$

Case of heterogeneous servers. In the case where $n-k$ elementary service times follow a Pareto distribution with parameters $\alpha_1, k_1$ and $k$ elementary service times follow a Pareto distribution with rates $\alpha_2, k_2$. Let factor $g$ which is the slowdown factor such that $g = \frac{k_1 \alpha_2}{k_2 \alpha_1}$. With these assumptions, the response time of $S$ is as follows:

$$E(T_{par}^{flow}) = R_1 + R_2$$

$$R_1 = (n-k)\alpha_1 k_1 n \sum_{m=0}^{n-1} \sum_{j=0}^{m} (-1)^m k^{-(j+1)\alpha_2} (k^a)^m \frac{\sum_{j=1}^{n-1} \alpha_j + \alpha_2 - 1}{\sum_{j=1}^{n-1} \alpha_j + \alpha_2 - 1}$$

$$R_2 = k\alpha_2 k_2^a \sum_{m=0}^{n-1} \sum_{j=0}^{m} (-1)^m k^{-(j\alpha_1 + (m-1)\alpha_2 - 1)} \frac{\sum_{j=1}^{n-1} \alpha_j + \alpha_2 - 1}{\sum_{j=1}^{n-1} \alpha_j + \alpha_2 - 1}$$

This equation (7) is easily derived by the equation (5) by considering that $(\alpha_i, k_i) = (\alpha_1, k_1)$, $\forall i \in \{1, ..., n-k\}$ and $(\alpha_i, k_i) = (\alpha_2, k_2)$, $\forall i \in \{n-k+1, ..., n\}$.

C. Computation for the switch constructor

In this case, we consider that we have one choice of $n$ elementary Web services. Let $P(Y = i)$ the invocation probability of elementary Web service $i$, with $\sum_{i=1}^{n} P(Y = i) = 1$. The response time of switch constructor is then given by the following analytic formula:

$$E(T_{switch}) = \sum_{i=1}^{n} P(Y = i) E(T_i)$$

with $E(T_i)$ the mean response time of service $i$.

Proof: First we calculate the probability density function of the random variable $T_{switch}$. The cumulative distribution function of the variable $T_{switch}$ is defined as: $F_{T_{switch}}(t) = P(T_{switch} \leq t)$. According to the total probability theorem, we have:

$$F_{T_{switch}}(t) = \sum_{i=1}^{n} P(T_{switch} \leq t \mid Y = i) P(Y = i)$$

The definition of the average of $T_{switch}$ allow to deduce the result given in equation (8).

Case of Pareto distribution. As in this paper, we consider the case of exponential distribution time for each elementary service time, thus the formula for mean response time is given by:

$$E(T_{par}) = n:\kappa^\alpha \sum_{i=1}^{n} \frac{\alpha_k}{\alpha_i - 1} P(Y = i)$$

In the next section, we are interested to multi-choice pattern which is not supported directly by BPEL, but it can be implemented using the links controls inherited from WSFL.

V. COMPUTATION FOR THE multi-choice PATTERN

The difference with the previous pattern where only one Web service is chosen, the multi-choice pattern allows the invocation of a subset of elementary services among the $n$ possible. Take for example the case of a booking flights operated as follows: Web services invoked depend on two criteria namely the city of departure and destination. Next, according to these cities, agencies providing this trip are invoked on parallel. The number of services, and relied on is random. Let $N$ the random variable for the number of invoked services and $P(N = i)$ the probability that the number of invoked service is equal to $i$, with $n$ maximum number of the invoked services. In this case, the response time of composite web service $S$ is given by the following formula:

$$E(T_{multichoice}) = \sum_{i=1}^{n} P(N = i) E(T_{S(i)})$$

Where $E(T_{S(i)})$ is the mean response time for composite Web service $S$ when $i$ elementary services are invoked.

Proof: First we give the cumulative function $F_{T_{multichoice}}(t)$ of random variable $T_{multichoice}$.

$$F_{T_{multichoice}}(t) = P(T_{multichoice} \leq t)$$

From total probability theorem, we can obtain:

$$F_{T_{multichoice}}(t) = P(\bigcup_{i=1}^{n} \{P(T_{multichoice} \leq t) \land N = i\})$$
We can derive the probability density $f_{T_{\text{multichoice}}}$ of $T_{\text{multichoice}}$ as:

$$f_{T_{\text{multichoice}}}(t) = \sum_{i=1}^{n} P(T_{\text{multichoice}} \leq t \mid N = i)P(N = i)$$

Thus, the cumulative function of $T_{\text{multichoice}}$ is:

$$F_{T_{\text{multichoice}}}(t) = \sum_{i=1}^{n} P(T_{\text{multichoice}} \leq t)P(N = i)$$

The case of homogenous servers.

As we consider the case of composite Web service $S$ distributed with $(\alpha, k)$ parameters and the invocation probability of elementary service $s_i$ is $p$, the mean response time $E(T_{\text{par}})$ can be easily derived as:

$$E(T_{\text{par}}) = \sum_{i=1}^{n} \sum_{j=1}^{n} C^{n}_{i} p^{j}(1-p)^{n-j} \gamma(i)$$

Where:

$$\gamma(i) = i \alpha k^i \sum_{m=0}^{i-1} (-1)^m \frac{k^{-(m+1)\alpha-1}}{(m+1)\alpha - 1} C^{m}_{i-1}$$

The case of heterogeneous servers.

We give also the analytical formula for composite Web service response time where we consider two classes of elementary services. The execution time in each class is the same. $N^1$ (resp. $N^2$) is the random variable which defined the number of elementary services in class 1 (resp. class 2). The mean response time formula is also derived from equation (11) and is given by:

$$E(T_{\text{par}}) = \sum_{i=1}^{n} P(N^1 = i) \sum_{j=0}^{\min(k, i)} E(T_{\text{multichoice}}(i, j)) P(N^2 = j \mid N^1 = i)$$

VI. EXPERIMENTAL RESULTS AND DISCUSSIONS

In this section, we present some numerical computation and results that we have obtained. When two class of services are considered, let first define a heterogeneous coefficient noted $g$, such as $\frac{k+\alpha}{-\alpha^2} = g \frac{k+\alpha}{1-\alpha}$ (the mean response time of elementary Web services belong respectively to class one and two). It is clear that if $g = 1$, then all of elementary Web services belong to the same class (i.e. the elementary Web services are homogenous). However, if $g > 1$ means that Web services belong to the second class are slower than services belong to the first class. For simplicity, we assume that the probability of elementary Web services invocation is $p$ for all services.

The synchronisation time, when $g = 1$, is the same for any value for the number of elementary Web services belong to the second class denoted $N^2$. In figure 1, we give the response times by varying the slowdown factor $g$ and where we consider different values of the number of elementary services for second class which takes these values $N^2 = 20$, $N^2 = 60$, $N^2 = 80$ and $N^2 = 100$. In figure 2, we give the response times by varying the the number of elementary services for second class and we consider the case of $g = 2$, $g = 3$, $g = 4$ and $g = 5$. From figure 1, we can conclude two things. First, for any value of $N^2$, the synchronization response time increases logarithmically with the heterogeneous coefficient $g$. Second, when $g = 1$ the response time of the composite Web service is the same for any value of the elementary Web services belong to the second class. From figure 2, we can notice that the waiting time increase logarithmically with invocation probability $p$. It is clear that the response time increases logarithmically with the number of invoked Web services (see figure 3). So, we can conclude that the choice of elementary Web services must be made on their physical characteristics and not on their number.

In the figure 4, we shown the evolution of $T_{\text{par}}^p$, where $T_{\text{exp}}$ and $T_{\text{par}}$ is the response time of a composite Web services when respectively the response time of elementary Web services is exponential and heavy-tailed. The results...
VII. CONCLUSION

Web Services are based on a set of standards and protocols, that allow us to make processing requests to remote systems by exchanging with a common language, and using common transport protocols. Once deployed, Web services provided can be combined (or inter-connected) in order to implement business collaborations, leading to composite web services. With the proliferation of Web Services as a business solution to enterprise application integration, the quality of service offered by Web Services is becoming the utmost priority for service provider and their partners. The QoS is defined as a combination of the different attributes of the Web services such as availability, response time, throughput, etc. In this paper, we have focused in the response time of composite Web services. We have proposed analytical formulas for the mean response of the different control patterns supported by BPEL standards. In this paper, we have studied the Pareto distribution. It is justified by the fact that experimental studies shown that Web services response time is typically heavy-tailed. However, the methodology can be applied to other service response time distributions.

We plan to consider the dynamic composition of Web services and we will give the analytical formulas for BPEL constructors as a perspective study.
